Alzheimer’s disease

A topic in the Alzheimer’s Association® series on understanding dementia.

About dementia
Dementia is a general term for a decline in mental ability severe enough to interfere with daily life. Dementia is not a single disease; it’s the umbrella term for an individual’s changes in memory, thinking or reasoning. There are many possible causes of dementia, including Alzheimer’s. Disorders grouped under the general term “dementia” are caused by abnormal brain changes. These changes trigger a decline in thinking skills, also known as cognitive abilities, severe enough to impair daily life and independent function. They also affect behavior, feelings and relationships.

Brain changes that cause dementia may be temporary, but they are most often permanent and worsen, leading to increasing disability and a shortened life span. Survival can vary widely, depending on such factors as the cause of the dementia, age at diagnosis and coexisting health conditions.

Alzheimer’s disease
Alzheimer’s disease is not a normal part of aging — it is a progressive brain disease that causes problems with memory, thinking and behavior. Alzheimer’s is the most common cause of dementia, accounting for 60% to 80% of dementia cases. Although there is currently no cure for Alzheimer’s, researchers are paving the way for future treatments by uncovering new insights into the biology of the disease.

Risk factors
Researchers believe there is not a single cause of Alzheimer’s disease. It likely develops from multiple factors, such as genetics, lifestyle and environment. Scientists have identified factors that increase the risk of Alzheimer’s. While some risk factors like age, family history and genetics can’t be changed, emerging evidence suggests there may be other factors people can influence.

Age
The greatest risk for Alzheimer’s disease is age. After age 65, a person’s risk of developing the disease doubles every five years. Thirty-two percent of people age 85 or older have Alzheimer’s.
Family history
Researchers have learned that people who have a parent, brother or sister with Alzheimer’s are more likely to develop it than those who do not. The risk increases if more than one family member has the disease.

Genetics
Two types of genes influence whether a person develops a disease: risk genes and deterministic genes. Risk genes increase the chance of developing a disease but do not guarantee it will happen. Deterministic genes cause a disease. This means anyone who inherits a deterministic gene will develop a disorder.

Rare deterministic genes cause Alzheimer’s in a few hundred extended families worldwide. Scientists estimate these genes cause less than 1% of cases. Individuals with these genes usually develop symptoms in their 40s or 50s.

Hispanic people, Black Americans and women
Research shows that older Hispanics are about one-and-a-half times as likely as older Whites to have Alzheimer’s and other dementias, while older Black Americans are about twice as likely. No one knows the exact reason for these differences, but researchers believe they are connected to higher rates of vascular disease in these groups.

Also, women live longer than men, making them more likely to develop Alzheimer’s. However, living longer doesn’t completely explain this difference. Researchers are exploring how genetic differences may impact disease risk.

Lowering the risk of cognitive decline
Age, family history and genetics are all risk factors that can’t be changed. However, research is offering clues about other risk factors that people may be able to influence. Studies show a strong connection between serious head injury and future risk of Alzheimer’s. For this reason, it is important to protect against head injury by wearing a seat belt in the car, wearing a helmet when playing sports and making sure the home is safe to avoid falls.
Research also shows there are healthy lifestyle habits that people can adopt to help keep their brain healthy and lower their risk of cognitive decline. These include eating a healthy diet, staying socially active, and exercising the body and the mind. Not using tobacco and avoiding excess alcohol is also good for brain health.

Science tells us there is a strong connection between brain health and heart health. The risk of developing Alzheimer’s or vascular dementia appears to be increased by many conditions that damage the heart and blood vessels. These include heart disease, diabetes, stroke, high blood pressure and high cholesterol.

**Symptoms and signs**
The symptoms of Alzheimer’s disease are more than simple lapses in memory or age-related changes. People living with Alzheimer’s disease experience memory loss as well as difficulties communicating, learning, thinking and reasoning. These are problems severe enough to interfere with an individual’s work, social activities and family life.

As the disease progresses, individuals may also experience changes in personality and behavior, such as anxiety, suspicion or agitation, as well as delusions or hallucinations.

In collaboration with experts in the field, the Alzheimer’s Association® created a list of warning signs to help people identify symptoms that may be related to Alzheimer’s or another form of dementia (alz.org/10signs). It is possible for individuals to experience one or more of these signs in varying degrees. It is not necessary to experience every sign in order to raise concern.

If you’re concerned that you or someone you know is displaying any of these signs, take action. It can be helpful to confide in a friend or family member. For tips on how to have a conversation, visit alz.org/memoryconcerns.

**Diagnosis**
Multiple conditions can cause cognitive changes, so it’s essential to obtain a full medical evaluation to determine whether symptoms are related to Alzheimer’s or something else. If the cause is not Alzheimer’s or another dementia, it could be a treatable condition. If it is dementia, there are many benefits to receiving an early and accurate diagnosis, including an opportunity to plan for the future, access support services and explore medication that may address some symptoms for a time.
There is no single diagnostic test that can determine if a person has Alzheimer’s disease. However, diagnostic tools and criteria make it possible for physicians to make a diagnosis of Alzheimer’s with about 90% accuracy. The diagnostic process may involve a thorough medical history, mental status and mood testing, a physical and neurological exam, and tests (such as blood tests and brain imaging) to rule out other causes of dementia-like symptoms. This process may take more than one day or visit. To learn more about the diagnostic process, visit alz.org/evaluatememory.

Treatments
The U.S. Food and Drug Administration (FDA) has approved medications that fall into two categories: drugs that may delay clinical decline in people living with Alzheimer’s, and drugs that may temporarily mitigate some symptoms of Alzheimer’s disease.

When considering any treatment, it is important to have a conversation with a health care professional to determine whether it is appropriate. A physician who is experienced in using these types of medications should monitor people who are taking them and ensure that the recommended guidelines are strictly observed.

Drugs that may delay clinical decline
An anti-amyloid antibody drug called aducanumab (Aduhelm™) may delay clinical decline in people living with Alzheimer’s disease by targeting beta-amyloid, a microscopic protein fragment that accumulates in the brain and forms into plaques. These plaques disrupt communication between nerve cells in the brain and may also activate immune system cells that trigger inflammation and devour disabled nerve cells. While scientists aren’t sure what causes cell death and tissue loss during the course of Alzheimer’s, amyloid plaques are one of the potential contributors, and preventing beta-amyloid buildup may provide benefit.

Drugs that treat symptoms
(Cognitive — memory and thinking — symptoms)
These medications are prescribed to treat symptoms related to memory and thinking. While these drugs cannot stop the damage Alzheimer’s causes to brain cells, they may help lessen or stabilize symptoms for a limited time by affecting certain chemicals involved in carrying messages between the brain's nerve cells.

The drugs currently approved to treat cognitive symptoms are cholinesterase inhibitors and glutamate regulators.

Non-cognitive (behavioral and psychological) symptoms
Alzheimer’s affects more than just memory and thinking. A person’s quality of life may be impacted by a variety of behavioral and psychological symptoms that accompany dementia, such as sleep changes.

Sleep changes may include difficulty sleeping, taking daytime naps and/or experiencing other shifts in sleep pattern. Learn more about sleep changes and available drug and non-drug treatments to address symptoms.

Suvorexant (Belsomra®) is the first medication approved specifically to treat insomnia in people living with Alzheimer’s. It works by blocking the activity of a chemical messenger involved in the sleep-wake cycle. It is important to try non-drug strategies to manage non-cognitive symptoms — like sleep changes — before adding medications.

Progression
Alzheimer’s disease typically progresses slowly in three general stages: early, middle and late (sometimes referred to as mild, moderate and severe in a medical context). Since Alzheimer’s affects people in different ways, each person may experience symptoms — or progress through the stages — differently. On average, people age 65 and older live four to eight years after diagnosis, while some live with the disease for as long as 20 years. Aside from the presence of additional health problems such as heart disease or diabetes that can shorten life span, researchers do not know why some people live longer than others.

The thinking, memory, behavioral and functional problems associated with Alzheimer’s reflect the areas of the brain affected by the disease. Areas involved with
learning and memory are usually affected first. Later, regions involved in planning and carrying out tasks are affected. Ultimately, the brain regions involved in carrying out basic bodily activities such as walking and swallowing are impaired, causing people in this stage to be bed-bound.

In general, those diagnosed when thinking and memory problems are still mild are likely to live with the disease for many years. Those diagnosed when problems are more pronounced, such as when the individual struggles to remember where they are or to dress correctly for the season, are likely to live with the disease for fewer years. Those diagnosed when problems are severe, such as needing help with dressing and eating, generally live for the shortest period. Eventually, the person with Alzheimer’s will need around-the-clock care. The disease is ultimately fatal.

Current Alzheimer’s statistics
- More than 6 million Americans are living with Alzheimer’s disease.
- Alzheimer’s kills more than breast cancer and prostate cancer combined.
- One in 3 seniors dies with Alzheimer’s disease.
- By 2050, the number of people age 65 and older living with Alzheimer’s is projected to reach 12.7 million.
